Abstract

Group testing is an indispensable tool for laboratories when testing high volumes of clinical specimens for infectious diseases. An important decision that needs to be made prior to implementation is determining what group sizes to use. In best practice, an objective function is chosen and then minimized to determine an optimal set of these group sizes, known as the optimal testing configuration (OTC). There are a few options for objective functions, and they differ based on how the expected number of tests, assay characteristics, and testing constraints are taken into account. These varied options have led to a recent controversy in the literature regarding which objective function is best. In our paper, we examine the most commonly proposed objective functions. We show that this controversy may be much ado about nothing because the OTCs and corresponding results (e.g., number of tests, accuracy) are largely the same for standard testing algorithms in a wide variety of situations.

1. Introduction

Laboratories throughout the world test high volumes of clinical specimens for infectious diseases, including HIV, hepatitis C, and West Nile virus. In such situations, it has become standard practice to test amalgamations of specimens as a "group" or "pool" rather than to test individual specimens. The reason is simple: members of a negative testing group can be declared negative all at once. Thus, for a group of size I, say, just one test is needed to declare all members negative, rather than the I separate tests that would be needed with individual testing. Fortunately, when disease prevalence is small, the majority of groups will test negatively when sensibly chosen group sizes are used. For members of a positive testing group, there are many algorithmic retesting procedures available to determine which specific individuals are positive. The first retesting procedure was proposed by Dorfman[1] and simply involved individually retesting each member of a positive group. Since this seminal work, group testing has been used to efficiently test for infectious diseases in a vast number of human applications, including blood donation screening,[2] antiretroviral treatment failure detection for HIV-positive individuals,[3,4] chlamydia and gonorrhea testing,[5] and influenza outbreak surveillance.[6] Outside of infectious disease testing in humans, group testing is used in an extensive number of applications, including cow milk surveillance,[7] disease detection in cattle and buffaloes,[8] West Nile virus monitoring in mosquitoes,[9] food contamination detection,[10] drug discovery,[11] and diagnosis of faulty network sensors.[12]

For all group testing applications, the choice of group sizes is extremely important for success. Choosing group sizes too large will lead to exceedingly many groups testing positively. This will subsequently lead to a large number of retests, perhaps even a larger number of tests overall than what would be needed for individual testing. Similarly, choosing group sizes too small will

lead to a larger number of tests than would otherwise be needed if the group sizes were chosen better. In best practice, laboratories choose group sizes by minimizing an objective function that takes into account the group testing algorithm to be implemented. There are a number of different algorithms in use, and they are best characterized as being either hierarchical or non-hierarchical in nature. Hierarchical algorithms begin by testing individuals in non-overlapping groups. For a group that tests positively, subsequent retesting stages occur in smaller, non-overlapping groups. The previously described Dorfman algorithm is a two-stage algorithm. Three- and four-stage algorithms are commonly used in practice [13,14] because they are often more efficient (i.e., fewer tests). Non-hierarchical algorithms involve testing each individual in overlapping groups to reduce the number of retests. The most common type of non-hierarchical algorithm is known as array testing. [15,16] For this algorithm, individual specimens are arranged in a two-dimensional grid. These specimens are amalgamated by row and by column and then tested. Intersecting positive rows and columns indicate where retesting should be performed to determine which individuals are positive. For a thorough review of hierarchical and array testing algorithms, see Hughes-Oliver. [17]

While there are many different types of group testing algorithms, all laboratories are interested in minimizing the number of tests needed to assay their specimens. For this reason, objective functions are based on the expected number of tests, so that a set of group sizes for a testing algorithm, known as the optimal testing configuration (OTC), can be found by minimizing this function. Traditionally, group testing research has focused on objective functions expressed solely as the expected number of tests per individual. This is due to a close correspondence between the number of tests and testing costs. However, using an objective function that contains only the expected number of tests leaves out an important component of infectious disease testing: accuracy. Infectious disease testing is rarely perfect. Errors can occur for reasons such as improper laboratory implementation or a specimen being collected during the window period between disease contraction and the ability to detect it. Fortunately, known mathematical expressions are available for the accuracy of most group testing algorithms. This enables laboratories to calculate the expected accuracy of a chosen testing configuration prior to implementation.

Malinovsky et al [18] recently proposed a new objective function that includes the expected number of tests and a measurement of accuracy. This allows laboratories to evaluate accuracy at the same time as the number of tests when choosing an OTC. As may be expected when breaking with tradition, the proposal generated controversy in the group testing research literature. Both Hudgens [19] and McMahan et al [20] offered rejoinders to Malinovsky et al [18] that disagreed with this new objective function. All three of these works focused only on the Dorfman algorithm in their limited evaluations. The purpose of our paper is to examine a significant number of other group testing algorithms with respect to objective functions. This is important because other algorithms are widely used and known to result in a smaller number of tests and/or higher accuracy than the Dorfman algorithm. We present findings in our paper that interestingly show both the traditional and the new objective function are actually quite similar and very often lead to the same OTC.

The order of this paper follows. Section 2 explicitly defines the objective functions and provides a mathematical comparison between them. Section 3 calculates the OTC for each objective function along with their operating characteristics (expected number of tests and accuracy measures) in a wide variety of settings. These calculations are performed for both hierarchical and array testing algorithms. We show under what conditions these operating characteristics will be the same and when they will be different. Section 4 summarizes our findings, discusses alternative objective functions, and provides recommendations for practice. We also provide R functions to find the OTCs and to reproduce our work.

2. Objective Functions

Define T as a random variable representing the total number of tests for an overall group of size I with a hierarchical algorithm. When using the traditional objective function, the OTC is found by minimizing the expected number of tests per individual:

$$O_{ET} = E(T)/I.$$

For example, the expected number of tests for three-stage hierarchical testing is given by

$$E(T) = 1 + m_{11}P(G_{11} = 1) + \sum_{j=1}^{c_2} m_{2j}P(G_{11} = 1, G_{2j} = 1),$$

where G_{sj} is the binary random variable (values of 1 and 0 indicate a positive and a negative test result, respectively) representing the outcome for group j at stage s, m_{sj} is the number of subgroups that would be created if group j at stage s tests positively, and c_s is the number of groups at stage s (see Black et al [21]; an example diagram is given in the Supporting Information available online to further explain the notation). The probabilities $P(G_{11} = 1)$ and $P(G_{11} = 1, G_{2j} = 1)$ are both functions of the number

of groups and their respective sizes, the probability of being positive for each individual, and the sensitivity S_e and specificity S_p of the assay. We do not provide further detailed expressions for $E(T)$ here to avoid distraction from the main points of our paper and because expressions are already provided elsewhere. For example, Kim et al[16] provides expressions for the case of each individual having the same true probability of being positive, say p, and Black et al[21] provides expressions for the case of each individual potentially having a different probability of being truly positive, say p_i for $i = 1, \ldots, I$. The latter case is known as informative group testing,[22,23,24] because p_i can be estimated with the help of disease-risk information that may be available for each individual tested. We will refer to the former case then as non-informative group testing in our work here. Expressions for the expected number of tests are known for array testing algorithms[16,25] as well, where O_{ET} is still defined as the expected number of tests per individual.

While O_{ET} is the most commonly utilized objective function, it does not directly take into account the accuracy of the algorithm. One usually examines its accuracy separately through various measures to judge if it is satisfactory. As an alternative approach, Malinovsky et al[18] proposed an objective function that simultaneously takes into account accuracy and the expected number of tests. To examine the accuracy aspect, define Y_i as the final positive/negative (1/0) outcome based on the group testing algorithm, and define $\tilde{Y}_i$ as the true positive/negative (1/0) status of individual i, for $i = 1, \ldots, I$. Commonly used accuracy measures for a group testing algorithm are the pooling sensitivity $PS_{e,i} = P(Y_i = 1|\tilde{Y}_i = 1)$ and the pooling specificity $PS_{p,i} = P(Y_i = 0|\tilde{Y}_i = 0)$ for individual i. As an overall measure of accuracy, define C as the number of correct classifications for a group of size I. The expected number of correct classifications is

$$\begin{aligned} E(C) &= \sum_{i=1}^{I} P(Y_i = 0, \tilde{Y}_i = 0) + P(Y_i = 1, \tilde{Y}_i = 1) \\ &= \sum_{i=1}^{I} PS_{p,i}(1 - p_i) + PS_{e,i}p_i, \end{aligned} \tag{1}$$

where $P(\tilde{Y}_i = 1) = p_i$ is the probability that individual i is truly positive.

Malinovsky et al[18] proposed to find the OTC by maximizing the expected number of correct classifications per individual divided by the expected number of tests per individual. Equivalently, this results in minimizing

$$O_{MAR} = E(T)/E(C).$$

Because C is never larger than the number of individuals I, $E(C) \leq I$. By comparing O_{MAR} and O_{ET}, we see that

$$O_{ET} = \frac{E(T)}{I} \leq \frac{E(T)}{E(C)} = O_{MAR}$$

for the same initial group size I. In fact, O_{MAR} and O_{ET} will be quite close in value. This is because infectious disease assays will only be put into use if they have high accuracy. Thus, $E(C)$ will be quite close to I in practice.

To examine this closeness more precisely, consider minimizing the logarithm of each objective function:

$$\log(O_{ET}) = \log\{E(T)\} - \log(I)$$

and

$$\log(O_{MAR}) = \log\{E(T)\} - \log\{E(C)\}. \tag{2}$$

For hierarchical testing, the pooling sensitivity is always the same for every individual tested in the same number of stages.[16,21] The pooling specificity is the same for every individual as well, but only for non-informative group testing with equal group sizes within a stage. Under this scenario then, we can simplify the expression for the expected number of correct classifications to be

$$E(C) = I\left\{PS_p(1 - p) + PS_e p\right\}, \tag{3}$$

where PS_p and PS_e are the pooling specificity and sensitivity, respectively, but now equal for each individual. For array testing, the same simplification for $E(C)$ from Equation (1) to Equation (3) occurs when the number of rows and the number of columns are the same (i.e., a square array), which is how array testing is usually applied.

By substituting Equation (3) into Equation (2), we obtain

$$\begin{aligned} \log(O_{MAR}) &= \log\{E(T)\} - \log\left[I\left\{PS_p(1 - p) + PS_e p\right\}\right] \\ &= \log(O_{ET}) - \log\left\{PS_p(1 - p) + PS_e p\right\}. \end{aligned}$$

Thus, any difference between the OTCs for the two objective functions is due to the "penalty" of

$$\log\left\{PS_p(1-p)+PS_ep\right\}. \tag{4}$$

Unfortunately, further definitive statements cannot be made regarding Equation (4), and we are left with making general statements regarding what will happen most often. In particular, we see that the penalty places a large weight on PS_p in comparison to PS_e because p is small for realistic group testing applications. Also, because PS_p and PS_e tend to be close to 1 for realistic applications, the penalty tends to be close to 0. Thus, $\log(O_{MAR})$ will most often be close to $\log(O_{ET})$.

3. Comparisons

Because definitive statements are not possible for Equation (4) or for the more general cases of unequal group sizes and informative group testing, we provide in this section a thorough investigation of the OTCs when using the objective functions over a very large number of situations. For each of these situations, we calculate the OTCs along with corresponding operating characteristics. Our results for both non-informative and informative group testing algorithms are described next.

3.1. Non-informative group testing

We include in this investigation the following group testing algorithms: two-stage hierarchical, three-stage hierarchical, array testing without a master pool (row and column groups are tested first, as described in Section 1), and array testing with a master pool (all specimens in the array are tested together in one group before any row or column groups are formed). For the first three algorithms, we allow the initial group sizes to range from $I = 3, ..., 40$, but allow higher initial group sizes when the overall prevalence is very small (e.g., $p = 0.005$) so that the OTC does not include our arbitrary upper bound for I. For array testing with a master pool, we use the same range of group sizes for the row and column groups, leading to a maximum master pool size of I^2. All array testing algorithms use square arrays, and we account for potential testing ambiguities that can occur in arrays (e.g., a row tests positively without any columns testing positively) by the methods described in Kim et al.[16] We apply these group testing algorithms over thirty different values of p ranging from 0.005 to 0.150 by 0.005 and over three separate sets of accuracy levels (low: $S_e = S_p = 0.90$, medium: $S_e = S_p = 0.95$, and high: $S_e = S_p = 0.99$). These values of p, S_e, and S_p are chosen because they correspond to when group testing is used for infectious disease testing. The assay accuracies are assumed to not change based on group size, meaning that they have been properly tested and calibrated.

Table 1 displays the results for $p = 0.01$. The OTCs are the same for both objective functions when using the hierarchical algorithms. Some small differences between OTCs exist for the array testing algorithms, but the differences are not of practical importance. For example, examine the results for array testing without master pooling and $S_e = S_p = 0.90$. The expected number of tests and the pooling sensitivities are the same to four decimal places. The pooling specificities are also quite close. In practical terms, for a testing load of 100,000 individuals, there would be 98,267 correct negatives found when using the OTC for O_{ET} and 98,307 correct negatives found when using the OTC for O_{MAR}. While 40 additional false positives would result from the OTC for O_{ET}, these false positives would most likely be discovered from follow-up confirmatory testing that normally would occur. We also provide similar tables for $p = 0.05$ and $p = 0.10$ in the Supporting Information available on the publisher's website. These tables show no differences among the OTCs when using either O_{ET} or O_{MAR}.

Table 2 summarizes the largest differences among the operating characteristics across all thirty different values of p included in our investigation. Most often, the OTCs found are the same for the two objective functions. When differences exist, these differences occur more often for smaller values of S_e and S_p, but again are not of practical importance. Overall, these findings help confirm what was strongly suspected in Section 2 through our mathematical analysis. Namely, the objective functions lead to the same OTCs or OTCs with similar operating characteristics when differences exist.

3.2. Informative group testing

We include in this investigation the following group testing algorithms: two-stage hierarchical implemented via the pool-specific optimal Dorfman (PSOD) method,[26] three-stage hierarchical,[21] and array testing without a master pool implemented via the gradient method.[25] For the PSOD method, we use a block size of 50 and replace its greedy optimization algorithm with examination of all possible testing configurations. Array testing with a master pool is not included in our investigations because there

have been no informative group testing algorithms proposed for it. We continue to allow the initial group sizes to range from $I = 3, ..., 40$ and allow for higher initial group sizes when the overall prevalence is very small.

To provide different levels of heterogeneity among the p_i for $i = 1, \ldots, I$, we use the expected value of order statistics from $P_i \sim \text{beta}\{\alpha, \alpha(1-p)/p\}$ for $i = 1, \ldots, I$ in the same manner as in Black et al.[21] This beta distribution has $E(P_i) = p$, and we once again consider values of p ranging from 0.005 to 0.150 by 0.005. The amount of heterogeneity is controlled by α, where lower levels indicate a larger amount of heterogeneity (see Black et al[21] for further discussion regarding the choice of α).

Table 3 displays the results for $E(P_i) = 0.01$, and the Supporting Information available on the publisher's website provides the results for $E(P_i) = 0.05$ and $E(P_i) = 0.10$. The displayed pooling sensitivity, PS_e^W, and pooling specificity, PS_p^W, are weighted averages of individual pooling sensitivities and pooling specificities, respectively, for all individuals within the initial group for a hierarchical algorithm or within the entire array for an array testing algorithm. Expressions for these averages are provided in the Supporting Information on the publisher's website and are based on accuracy definitions given by Altman and Bland.[27] The largest differences for each operating characteristic across all values of p are given in Table 4. Overall, while differences exist more often for some algorithms than in the non-informative group testing setting, O_{ET} and O_{MAR} still result in the same or very similar OTCs the majority of the time, and, when differences exist, the differences likely would not be of practical importance due to similar operating characteristic values.

4. Conclusion

We have shown that the choice between the O_{ET} and O_{MAR} objective functions most often does not change the OTC, and even when the OTC is different, there are not practical differences in the operating characteristics. Therefore, our work helps to close the case on the recent controversy regarding objective functions: they both can be used in practice. However, we tend to favor the traditionally used O_{ET} for one main reason. Simply, laboratories need to know the number of tests to be expected and the corresponding costs involved. In many instances, the expected costs are directly proportional to the expected number of tests. While the expected number of tests could also be stated when using O_{MAR}, this seems to be an unnecessary extra step, especially for laboratory directors and technicians who choose the OTC. For these users and also for those performing research in the area, we make available a set of R functions in the `binGroup` package that can be used to find the OTC with O_{ET} or O_{MAR}. Examples of how to use these functions are available on our research website at www.chrisbilder.com/grouptesting and in the Supporting Information for this paper on the publisher's website.

Throughout this paper, we had to make the assumption that p or p_i for $i = 1, \ldots, I$ is known. Of course, this would not be known in actual practice. Instead, some type of past experience would be used by laboratories to estimate these quantities so that an "estimated" OTC could be chosen. These estimated OTCs still would be the same or very similar for the two objective functions because the same estimates for probabilities of being positive would be used with each function. Furthermore, even when there would be small differences among OTCs, these differences would have less meaning in practice due to the true probabilities being unknown.

There are other objective functions that could be used. For example, Malinovsky et al[18] considered maximizing $E(C/T)$, but concluded this to be inferior to O_{MAR}. Therefore, we focused only on their O_{MAR} proposal in our paper. Other objective functions can include weights or penalties for making classification errors. For example, Graff and Roeloffs[28] proposed using an objective function that is a linear combination of the expected number of tests, the number of misclassified negatives, and the number of misclassified positives. Subjectively chosen weights are used with the misclassification measures to increase or decrease their importance. Of course, there will be weights then that result in an OTC which is quite different than what would be obtained from using O_{ET} and O_{MAR}, making the outcome in that case much ado about something. However, the subjectiveness of these weights can depend on the infectious disease, the laboratory, or even particular individuals at a laboratory. Therefore, for general applications and research settings, it is difficult to use this or similar types of objective functions. For this reason, we do not examine this particular objective function in our paper.

ACKNOWLEDGEMENTS

TABLE 1 OTC summary for $p = 0.01$ under non-informative group testing. Equally sized groups are optimal at each stage; thus, an OTC of "24-6-1" means that stage 1 has a group of size 24, stage 2 has four groups of size 6, and stage 3 has twenty-four groups of size 1. Differences between O_{ET} and O_{MAR} are highlighted.

Algorithm	S_e	S_p	Objective function	OTC	$E(T)/I$	PS_e	PS_p
2-stage hierarchical	0.99	0.99	O_{ET}	11-1	0.2035	0.9801	0.9990

TABLE 2 Largest differences between operating characteristics for OTCs under non-informative group testing. Values of p range from 0.005 to 0.150 by 0.005. The frequency column denotes the number of times a different OTC was found for O_{ET} and O_{MAR} among these values of p. Differences between operating characteristics are rounded to four decimal places. Note that operating characteristics are always smaller for O_{ET} than for O_{MAR} when differences exist.

TABLE 3 OTC summary for $E(P_i) = 0.01$ under informative group testing. Multiple initial group sizes for 2-stage hierarchical algorithms are found within a block size of 50, so they are not displayed here. The full OTCs are provided in the Supporting Information available on the publisher's website. Differences between O_{ET} and O_{MAR} are highlighted.

TABLE 4 Largest differences between operating characteristics for OTCs under informative group testing. Values of $E(P_i) = p$ range from 0.005 to 0.150 by 0.005. The frequency column denotes the number of times a different OTC was found among these values of p. Differences between operating characteristics are rounded to four decimal places. Note that the operating characteristic value for O_{ET} is always subtracted from the operating characteristic value for O_{MAR}. Thus, a negative value (indicated with parentheses) means that the value for O_{ET} was larger than the value for O_{MAR}.
